9.2 Secant Method, False Position Method, and Ridders' Method

For functions that are smooth near a root, the methods known respectively as *false position* (or *regula falsi*) and the *secant method* generally converge faster than bisection. In both of these methods the function is assumed to be approximately linear in the local region of interest, and the next improvement in the root is taken as the point where the approximating line crosses the axis. After each iteration, one of the previous boundary points is discarded in favor of the latest estimate of the root.

The *only* difference between the methods is that secant retains the most recent of the prior estimates (Figure 9.2.1; this requires an arbitrary choice on the first iteration), while false position retains that prior estimate for which the function value has the opposite sign from the function value at the current best estimate of the root, so that the two points continue to bracket the root (Figure 9.2.2). Mathematically, the secant method converges more rapidly near a root of a sufficiently continuous function. Its order of convergence can be shown to be the “golden ratio” 1.618..., so that

$$\lim_{k \rightarrow \infty} |\epsilon_{k+1}| \approx \text{const} \times |\epsilon_k|^{1.618} \quad (9.2.1)$$

The secant method has, however, the disadvantage that the root does not necessarily remain bracketed. For functions that are *not* sufficiently continuous, the algorithm can therefore not be guaranteed to converge: Local behavior might send it off toward infinity.

False position, since it sometimes keeps an older rather than newer function evaluation, has a lower order of convergence. Since the newer function value will *sometimes* be kept, the method is often superlinear, but estimation of its exact order is not so easy.

Here are sample implementations of these two related methods. While these methods are standard textbook fare, *Ridders' method*, described below, or *Brent's method*, described in the next section, are almost always better choices. Figure 9.2.3 shows the behavior of the secant and false-position methods in a difficult situation.

Figure 9.2.1. Secant method. Extrapolation or interpolation lines (dashed) are drawn through the two most recently evaluated points, whether or not they bracket the function. The points are numbered in the order that they are used.

Figure 9.2.2. False-position method. Interpolation lines (dashed) are drawn through the most recent points that bracket the root. In this example, point 1 thus remains “active” for many steps. False position converges less rapidly than the secant method, but it is more certain.

Figure 9.2.3. Example where both the secant and false-position methods will take many iterations to arrive at the true root. This function would be difficult for many other root-finding methods.

```
template <class T>
Doub rtfbsp(T &func, const Doub x1, const Doub x2, const Doub xacc) {
    const Int MAXIT=30;
    Doub x1,xh,del;
    Doub fl=func(x1);
    Doub fh=func(x2);
    if (fl*fh > 0.0) throw("Root must be bracketed in rtfbsp");
    if (fl < 0.0) {
        x1=x1;
        xh=x2;
    } else {
        x1=x2;
        xh=x1;
        SWAP(fl,fh);
    }
    Doub dx=xh-x1;
    for (Int j=0;j<MAXIT;j++) {
        Doub rtf=x1+dx*fl/(fl-fh);
        Doub f=func(rtf);
        if (f < 0.0) {
            del=x1-rtf;
            x1=rtf;
            fl=f;
        } else {
            del=xh-rtf;
            xh=rtf;
            fh=f;
        }
        dx=xh-x1;
        if (abs(del) < xacc || f == 0.0) return rtf;
    }
}
```

Using the false-position method, return the root of a function or functor func known to lie between x1 and x2. The root is refined until its accuracy is $\pm xacc$.

Set to the maximum allowed number of iterations.

Be sure the interval brackets a root.

Identify the limits so that x1 corresponds to the low side.

False-position loop.

Increment with respect to latest value.

Replace appropriate limit.

Convergence.

roots.h

        Doub f1=func(x1);
        Doub f=func(x2);
        if (abs(f1) < abs(f)) {        Pick the bound with the smaller function value as
            rts=x1;                    the most recent guess.
            x1=x2;
            SWAP(f1,f);
        } else {
            x1=x1;
            rts=x2;
        }
        for (Int j=0;j<MAXIT;j++) {    Secant loop.
            Doub dx=(x1-rts)*f/(f-f1);  Increment with respect to latest value.
            x1=rts;
            f1=f;
            rts += dx;
            f=func(rts);
            if (abs(dx) < xacc || f == 0.0) return rts;    Convergence.
        }
        throw("Maximum number of iterations exceeded in rtsec");
}

```

9.2.1 Ridders' Method

A powerful variant on false position is due to Ridders [1]. When a root is bracketed between x_1 and x_2 , Ridders' method first evaluates the function at the midpoint $x_3 = (x_1 + x_2)/2$. It then factors out that unique exponential function that turns the residual function into a straight line. Specifically, it solves for a factor e^Q that gives

$$f(x_1) - 2f(x_3)e^Q + f(x_2)e^{2Q} = 0 \quad (9.2.2)$$

This is a quadratic equation in e^Q , which can be solved to give

$$e^Q = \frac{f(x_3) + \text{sign}[f(x_2)]\sqrt{f(x_3)^2 - f(x_1)f(x_2)}}{f(x_2)} \quad (9.2.3)$$

Now the false-position method is applied, not to the values $f(x_1)$, $f(x_3)$, $f(x_2)$, but to the values $f(x_1)$, $f(x_3)e^Q$, $f(x_2)e^{2Q}$, yielding a new guess for the root, x_4 . The overall updating formula (incorporating the solution 9.2.3) is

$$x_4 = x_3 + (x_3 - x_1) \frac{\text{sign}[f(x_1) - f(x_2)]f(x_3)}{\sqrt{f(x_3)^2 - f(x_1)f(x_2)}} \quad (9.2.4)$$

Equation (9.2.4) has some very nice properties. First, x_4 is guaranteed to lie in the interval (x_1, x_2) , so the method never jumps out of its brackets. Second, the convergence of successive applications of equation (9.2.4) is *quadratic*, that is, $m = 2$

in equation (9.1.4). Since each application of (9.2.4) requires two function evaluations, the actual order of the method is $\sqrt{2}$, not 2; but this is still quite respectably superlinear: The number of significant digits in the answer approximately *doubles* with each two function evaluations. Third, taking out the function's "bend" via exponential (that is, ratio) factors, rather than via a polynomial technique (e.g., fitting a parabola), turns out to give an extraordinarily robust algorithm. In both reliability and speed, Ridders' method is generally competitive with the more highly developed and better established (but more complicated) method of van Wijngaarden, Dekker, and Brent, which we next discuss.

```
template <class T>
Doub zriddr(T &func, const Doub x1, const Doub x2, const Doub xacc) {
    Using Ridders' method, return the root of a function or functor func known to lie between x1
    and x2. The root will be refined to an approximate accuracy xacc.
    const Int MAXIT=60;
    Doub fl=func(x1);
    Doub fh=func(x2);
    if ((fl > 0.0 && fh < 0.0) || (fl < 0.0 && fh > 0.0)) {
        Doub xl=x1;
        Doub xh=x2;
        Doub ans=-9.99e99;
        for (Int j=0;j<MAXIT;j++) {
            Doub xm=0.5*(xl+xh);
            Doub fm=func(xm);
            Doub s=sqrt(fm*fm-fl*fh);
            if (s == 0.0) return ans;
            Doub xnew=xm+(xm-xl)*((fl >= fh ? 1.0 : -1.0)*fm/s);
            if (abs(xnew-ans) <= xacc) return ans;
            ans=xnew;
            Doub fnew=func(xnew);
            if (fnew == 0.0) return ans;
            if (SIGN(fm,fnew) != fm) {
                xl=xm;
                fl=fm;
                xh=ans;
                fh=fnew;
            } else if (SIGN(fl,fnew) != fl) {
                xh=ans;
                fh=fnew;
            } else if (SIGN(fh,fnew) != fh) {
                xl=ans;
                fl=fnew;
            } else throw("never get here.");
            if (abs(xh-xl) <= xacc) return ans;
        }
        throw("zriddr exceed maximum iterations");
    }
    else {
        if (fl == 0.0) return x1;
        if (fh == 0.0) return x2;
        throw("root must be bracketed in zriddr.");
    }
}
```

roots.h

Any highly unlikely value, to simplify logic below.

First of two function evaluations per iteration.

Updating formula.

Second of two function evaluations per iteration.

Bookkeeping to keep the root bracketed on next iteration.
